ABSTRACT

Many reconfigurable architectures offer partial dynamic configurability, but current system-level tools cannot guarantee feasible implementations when exploiting this feature. We present a physically aware hardware-software (HW-SW) scheme for minimizing application execution time under HW resource constraints, where the HW is a reconfigurable architecture with partial dynamic reconfiguration capability. Such architectures impose strict placement constraints that lead to implementation infeasibility of even optimal scheduling formulations that ignore the nature of these constraints. We propose an exact and a heuristic formulation that simultaneously partition, schedule, and do linear placement of tasks on such architectures. With our exact formulation, we prove the critical nature of placement constraints. We demonstrate that our heuristic generates high-quality schedules by comparing the results with the exact formulation for small tests and a popular, but placement-unaware scheduling heuristic for larger tests. With a case study, we demonstrate extension of our approach to handle heterogenous architectures with specialized resources distributed between general purpose programmable logic columns. The execution time of our heuristic is very reasonable- task graphs with hundreds of nodes are processed in a couple of minutes.

Categories and Subject Descriptors: B.6.3 [C.1.3]

General Terms: Algorithms

Keywords: HW-SW partitioning, partial dynamic reconfiguration, linear placement

1. INTRODUCTION

Dynamic reconfiguration, often referred to as RTR (run-time reconfiguration) provides the ability to change hardware configuration during application execution. This enables a larger percentage of the application to be accelerated in hardware, hence reducing overall application execution time [12]. Modern-day SRAM-based FPGAs are examples of such hardware devices. Additionally, some FPGAs such as the Virtex devices from Xilinx [17] allow modification of only a part of the configuration (partial RTR). This is a very powerful feature specially for single-context FPGAs, by enabling the possibility of overlapping computation with reconfiguration to reduce the significant reconfiguration time overhead. Multicontext devices such as Morpheus [5] incur a lower overhead by paying a very significant area penalty to simultaneously store multiple contexts. Our work focuses on single-context devices where the dynamic reconfiguration overhead is very significant.

In this work, we consider the problem of task level HW-SW partitioning for a resource-constrained system, where the HW device has partial RTR capability. In a traditional codesign flow, HW-SW partitioning optimizes the design latency- subsequently the physical design stage places the tasks scheduled to HW on the underlying device. However, our target system architecture imposes strict linear placement constraints. Under such constraints, even an optimal schedule generated without considering the exact physical location of the task [7], may be physically unrealizable because of placement infeasibility.

This work makes several contributions:

• We demonstrate that existing approaches that do not consider physical task layout can result in unrealizable (infeasible) designs.
• We outline an exact approach that incorporates physical layout.
• We present a KLFM heuristic incorporating detailed linear placement that generates good results on a large set of benchmarks.
• We show applicability of our work to heterogeneous architectures.

A key benefit of considering placement and multiple task implementations is the ability to extend our approach to consider heterogeneity with relatively minor modifications. Heterogeneity is a key aspect of modern reconfigurable architectures like the Virtex-II that contain dedicated resource columns of multipliers, block memories distributed between general purpose programmable logic columns. Such dedicated resources often lead to more area-efficient implementations that operate at a higher frequency. In a detailed case study of mapping a jpeg encoder task graph under resource constraints, we explore the benefits and issues with dynamic task implementations using heterogenous resources on such architectures.

2. RELATED WORK

HW-SW partitioning is an extensively studied problem with a plethora of approaches, including many KLFM-based approaches (Kernighan-Lin/Fiduccia-Matheyes, [15], [14]) such as [8], [11]. However, existing work often does not consider the special challenges posed by dynamic reconfiguration- partial RTR imposes more physical constraints that need to be incorporated explicitly.

Recently there has been work on simultaneous scheduling and placement for partially reconfigurable devices [1], [4]. However, they ignore key issues in run-time reconfiguration such as prefetch to overcome latency, the resource contention due to single reconfiguration controller, etc. With these simplifications, the problem becomes closer to rectangle packing [13]. Another approach to reducing the significant reconfiguration overhead is reuse, where the work often considers all tasks to be of equal area and focuses on exploiting similarity between a given set of scheduled tasks [2]. In
our work, we currently do not exploit such resource-sharing across tasks. We focus on integrating key architectural constraints and placement considerations into the scheduling formulation for the more realistic scenario of varying task sizes.

Our work is most closely related to [6] and [7]. Mei et al. [6] present a genetic algorithm for partial RTR that considers columnar task placement. However, their approach does not consider prefetch or the single reconfiguration controller bottleneck. Jeong et al. [7] present an exact algorithm (ILP) and a KLFM-based approach. Their ILP considers prefetch and the single reconfiguration controller bottleneck—however, while scheduling, they do not consider the critical issue of physical task placement. We will demonstrate that an optimal formulation that does not simultaneously consider placement while scheduling can generate schedules which can not be placed and hence are not physically realizable. Another distinctive feature of our work compared to existing work is our consideration of heterogeneity in resources, a key feature of modern reconfigurable architectures.

3. PROBLEM DESCRIPTION

We consider the problem of HW-SW partitioning of an application specified as a task dependency graph extracted from a functional specification in a high-level language like C, VHDL, etc. In a task dependency graph (Figure 2), each vertex represents a task that can start execution only when all its ancestors have completed.

Our target system architecture as shown in Figure 1 consists of a SW processor and a dynamically reconfigurable FPGA with partial reconfiguration capability. The processor and the FPGA communicate by a system bus. We assume concurrent execution of the processor and the FPGA. We assume that the dynamically reconfigurable tasks on the FPGA communicate via a shared memory mechanism—this shared memory can be physically mapped to local on-chip memory and/or off-chip memory depending upon memory requirements of the application. Under this abstraction, communication time between two tasks mapped to the FPGA is independent of their physical placement. Thus, when adjacent tasks in the task graph are mapped to the same device (processor or FPGA), the communication overhead is considered insignificant, while tasks mapped to different devices incur a HW-SW communication delay.

On such a system architecture, a task can have multiple implementations: as a simple example, compiler optimizations like loop unrolling often result in a faster implementation with more HW area. Another example is the possibility of a very area-efficient implementation using dedicated resources like embedded memory. Our objective is to minimize the execution time of the application while respecting the architectural and resource constraints imposed by the system architecture. Thus, our desired solution is a task schedule where each task is bound to HW or SW along with a suitable implementation point for each task.

Dynamically reconfigurable FPGA

Our target dynamically reconfigurable device as shown in Figure 3 consists of a set of configurable logic blocks (CLB) arranged in a two-dimensional matrix. Additionally, a limited number of
time $t_2$, 2 adjacent columns ($C_1$, $C_2$) would be available to place a 2 column task. However, the more detailed example in Figure 5 demonstrates that there are schedules that can not be placed by an optimal placement tool. At time step 9, task $T_{10}$ needs 4 columns for execution- even though there are 6 columns available in the FPGA, 4 contiguous columns are not available. Note that changing the task placement at prior time-steps (for example swapping physical location of task $T_j$ with task $T_k$) would only lead to placement failure at a previous time-step. To achieve a feasible placement, the task schedule itself needs to change. Therefore, it is critical to integrate linear placement of the tasks into the scheduling formulation in order to generate feasible solutions.

4.2 Heterogeneous implementations

Modern FPGAs (such as the Xilinx Virtex-II) have heterogeneous architectures containing columns of dedicated resources like embedded multipliers, embedded memory blocks. Usage of such specialized resources usually leads to more area-efficient and faster implementations. As an example, we consider post-routing timing data obtained from synthesizing a 2-dimensional DCT (discrete cosine transform) under columnar placement and routing constraints on the Virtex-II chip XC2V2000. While the heterogeneous implementation with 3 CLB columns and 1 resource column has an operating frequency of 88 MHz, the homogenous implementation with 4 CLB columns is able to operate at only 64 MHz (we consider the adjacent column pair of BRAM (embedded memory) and MULTX18 (embedded multiplier) as a single resource column for generating numerical data).

However, these heterogenous resources are typically limited in number and present in specific locations. For instance, XC2V2000 has 48 CLB columns, but only 4 heterogenous resource columns. Since these resource columns are available only at fixed locations, they impose stricter placement constraints. Depending on where a task is placed, the HW execution time and area may vary significantly. This provides further motivation for considering linear placement as an integral aspect of HW-SW partitioning on reconfigurable architectures.

4.3 Scheduling for configuration prefetch

Configuration pre-fetch [9] is a powerful technique that attempts to overcome the significant reconfiguration penalty in single-context dynamically reconfigurable architectures by separating a task into reconfiguration and execution components. While the execution component is scheduled after data dependencies from parent tasks in the task graph are satisfied, the reconfiguration component is not constrained by such dependencies. This poses a significant challenge to any scheduling formulation that incorporates prefetch.

5. PROPOSED APPROACH

First, we modify the problem description to address the previous issues: We have a task graph with $n$ tasks, where each task has multiple possible implementations. Each HW implementation of a task occupies a certain number of columns. We have one available SW processor, and a HW resource constraint of $m$ HW columns for application mapping. Our objective is to find an optimal schedule where each task is bound to HW or SW, the task implementation is fixed, and, for HW tasks, the physical task location is determined.

**ILP formulation:** To understand the problem space and determine optimality, we first formulated an ILP (integer linear program) with key 0-1 variables $x_{ijk}$ denoting execution of task $T_i$ at time step $j$, leftmost column $k$, $r_{ij}$ denoting reconfiguration of $T_i$, etc. The key constraints enforcing contiguity for multi-column tasks, configuration prefetch to reduce schedule length, resource constraints imposed by the single reconfiguration controller, etc. are explained in [16]. However, a commercial ILP solver (CPLEX) required an exorbitant amount of computation time to obtain an optimal solution even for relatively small problem instances. This motivated us to develop a heuristic approach that generates reasonably good-quality solutions with a computation effort many orders of magnitude lower– our heuristic generates quality solutions to problems with hundreds of tasks in a couple of minutes.

5.1 Heuristic formulation

Our approach is based on the well-known Kernighan-Lin/Fiduccia-Mattheys (KLFM) heuristic [15], [14] that iteratively improves solutions to "hard" problems by simple moves. At each step of the KLFM heuristic, the quality of a move needs to be evaluated. Similar to previous work in HW-SW partitioning such as [8], we evaluate the quality of a move by a scheduler. However, our target platform requires that our scheduler is specifically aware of the physical device architecture.

**Code segment 1:**

```
KLFM loop
while (more unlocked tasks)
    for each unlocked task
        for each non-current implementation point
            calculate makespan by physically aware list-scheduling
            select & lock best (unlocked task, implementation point) tuple
            update best partition if new partition is better
```

Code segment 1 represents the KLFM kernel: while there are more unlocked tasks, the "best" task is chosen in every iteration of the loop. The kernel is itself repeatedly executed $c$ times where $c$ is a small constant, around 5-6. As can be seen above, our kernel considers multiple task implementation. In simple cases where each task has a single HW and a single SW implementation, a "move" in HW-SW partitioning usually implies moving the task to the other partition. In task implementations on FPGAs, multiple area-time tradeoff points are very common. Restricting a move to only HW-SW, or vice-versa would restrict the solution space. Thus we define a move as generic, possible between *any two implementation points* of a task, including HW-HW, HW-SW.

For the scheduler, we choose a simple list-scheduling algorithm. In a list-scheduler, at each stage there is a set of 'ready' nodes whose parents have been scheduled. The scheduler chooses the 'best' node based on some priority measure– the schedule quality depends strongly on priority assignment of nodes. Note that the scheduler is embedded inside the partitioner; thus, the scheduler always sees a bound graph where each task is assigned to HW or SW and hence the HW-SW communication on each edge is known.

We do simultaneous scheduling and placement– once a node is selected for scheduling, it is immediately placed onto the device. This ensures that all generated schedules are correct by construction. Thus, at every KLFM step, along with task binding, we also have the placed schedule available.

In traditional resource-constrained scheduling, priority functions like "nodes on critical path first" are applied uniformly to all nodes. But, on our target HW, factors that affect placement, such as configuration prefetch, play a key role in scheduling. So we propose that during task selection, processor tasks are compared between themselves on the simple basis of longest path, while FPGA tasks are compared using a more complex function. Key parameters of any such function are EST (earliest computation start time of task), EFT (earliest finish time), task area, and the longest path through the task, i.e. the function can be described as: $f$ (EST, longest path, area, EFT). The EST computation embeds physical issues related to placement, resource bottleneck of single reconfiguration controller in the configuration prefetch process, etc., as described in more detail later.

Our observations indicate that it is usually more beneficial to first place tasks with narrower width (fewer columns): this leads
The goal is to complete reconfiguration of a single reconfiguration controller. The reconfiguration for rectangular packing algorithms from work like [13].

Underutilized. Since the extent of the interval can not be determined apriori, placement is complicated: if we consider the aggregate rectangle consists of both the execution and reconfiguration component of a task, this is a rectangle of unknown length. Thus, with prefetch, we are unable to directly apply rectangular packing algorithms from work like [13].

Another key issue in EST computation is the resource bottleneck of a single reconfiguration controller. The reconfiguration for a task can start only when enough area is available, and the reconfiguration controller is free. The goal is to complete reconfiguration before task dependencies are satisfied, leading to minimization of schedule length. However, realistically, it is not possible to hide the overhead for all tasks that need reconfiguration— in such cases, task execution is scheduled as soon as its reconfiguration ends.

In Code segment 2 we present our approach to EST computation that addresses the issues we discussed above. Our goal is to find the earliest time slot when the task can be scheduled, subject to the various constraints. We proceed by first searching for the earliest instant when we can have a feasible task placement, i.e. enough adjacent columns are available for the task. Once we have obtained a feasible placement, we proceed to satisfy the other constraints. If the reconfiguration controller was available at the instant the space becomes available, then the reconfiguration component of the task can proceed immediately. Otherwise, the reconfiguration component of the task has to wait till the reconfiguration controller becomes free. Once the reconfiguration component is scheduled, we check to see if the execution component can be immediately scheduled subject to dependency constraints. As an example, we consider EST computation of task T3 in Figure 7 when tasks T1 and T2 have been scheduled, and placed. The initial search shows a feasible placement starting at time 3 and the reconfiguration controller is free, so reconfiguration for T3 can start immediately and finishes at time 4. However, the execution component can be scheduled only at time 6 when its dependency is satisfied. In this case, EST computation indicates that it is possible to completely hide the reconfiguration overhead for the task.

The EST computation thus embeds the placement issues and resource constraints related to reconfiguration. As discussed earlier, the scheduler assigns task priorities based on this information, leading to high-quality schedules, as shown in our experimental section.

Code segment 2: Compute EST for task bound to FPGA

```plaintext
find earliest time slot where task can be placed
reconfig start = earliest time instant space and reconfig controller are simultaneously available.
if ((reconfig start + reconfig time) < dependency time) // reconfiguration latency hidden completely: possibility of timing gap between reconfig end and execution start
EST = earliest time parent dependencies satisfied
else // not possible to completely hide latency
EST = end of reconfiguration
```

5.2 Heterogeneity

One key benefit of considering linear placement and multiple task implementations in our heuristic is the ease with which we were able to extend our approach to consider scheduling onto heterogeneous devices.

To adapt our approach for heterogeneity, the primary change required is in the search for space to fit a task. We do this by simply adding a type descriptor for each column in our resource description. Thus all resource queries at a time instant check the column type descriptor while looking for free space at that instant. Some simple initial preprocessing makes the searches more efficient.

6. EXPERIMENTS

We conducted a wide range of experiments to demonstrate the validity of our formulation and the schedule quality generated by our heuristic. We also conducted a detailed case study of the JPEG encoding algorithm, where we explored heterogeneity in the context of multiple task implementation points. In this section we present a reasonable subset of our experiments—additional details are in [16]. Note that we are concerned with statically determining the best run-time schedule for a HW-SW system under resource constraints, where the HW has partial dynamic reconfiguration ca-

pability. Thus, while it is possible for example to fit all our JPEG
tasks in a suitably-sized device, for our experimental purposes we
assume a resource constraint less than the aggregate HW size of all
tasks leading to the necessity of HW-SW partitioning.

Experiments on feasibility

The following assumptions form the basis of our numerical data:

Area and timing data for key tasks like DCT, IDCT, was obtained by
synthesizing tasks under columnar placement and routing con-
straints on the XC2V2000, similar to the methodology suggested for
"reconfigurable modules". Software task execution time on the
PowerPC processor is typically 3 to 5 times slower than the HW
implementation of the task. HW-SW communication time was es-
imated by simply dividing the aggregate amount of data transfer
by the bus speed. As an example, data transfer time for a 256X256
block of 8-bit pixels in a typical image processing application is esti-
ated as: 256 * 256 * 8/64 cycles at 133 MHz = 0.06 ms.
Note that HW-SW communication time for even this significant
volume of data transfer is only around 30% of the reconfiguration
overhead for a single CLB column: thus, for generating synthetic
experiments, we assumed that HW-SW communication time was
quite low compared to task reconfiguration time.

Experiments on heuristic quality

Table 1 shows experimental results on feasibility for a set of
synthetic task-graphs and well-known graph structures like FFT,
meanval, etc. These test cases were reasonably small graphs with
between 10-15 vertices such that we could generate optimal results
with the ILP. For each test, we assumed that the number of columns
available for task mapping was approximately 20-30% of the aggre-
gate area of all tasks mapped to hardware. For these tests, one unit
der tim is the reconfiguration time for a single column.

In Table1, $T_{feas}$ denotes the schedule length obtained with our ILP
formulation, $T_{opt}$ denotes the schedule length obtained from an
exact formulation that considers available HW area instead of exact
task placement (i.e., placement-unaware) [7]. As Table1 shows, in
some cases, $T_{heu}$ is shorter than $T_{opt}$, but in these cases the sched-
ules were physically unrealizable with exact placement, while our
ILP ($T_{opt}$) guarantees placement through correct by construction.

Experiments on heuristic quality

For each of the initial set of experiments we also generated re-
results with our proposed heuristic, as denoted by $T_{heu}$ in Table 1. The

Experiments on heuristic quality

Table 2: Aggregate improvements in schedule length data indicates that for the small cases, $T_{heu}$ corresponds to schedules
that are reasonably close in quality to the exact solution.

For analysis of schedule quality generated by our heuristic on
larger test-cases, we generated a set of problem instances with suit-
able modifications to TGFF [10]. In these tests, each task had a
single homogenous implementation point. In subsequent discus-
sions, v20, v80, etc. denote sets of graphs that have approximately
20 nodes, 80 nodes, etc. For each individual test case belonging to a
set like v20, we varied the area constraint from 8 to 20 columns
in steps of 4 to generate a problem instance.

Figure 8: Sample experiments for v60

For each generated problem instance, we compared the schedule
length generated by our placement-aware heuristic with that gener-
ated by the placement-unaware "longest path first" (LPF) heuristic.
The LPF heuristic is widely used in resource-constrained schedul-
ing to assign higher priorities to tasks on critical paths. Note: LPF
is used only for priority assignment at each scheduling step-- once a
task is selected, the same linear placement approach ensures correct
schedules, and, hides the reconfiguration latency, if possible.

In Figure 8 we present a sample of the tests we conducted. For
two test graphs in set v20 we show schedule length data corre-
sponding to a total of 8 problem instances. To present the aggregate data
for the complete set of experiments, we define $T_{longest\_path}$ as the
schedule length generated by LPF for a problem instance. And,
the quality criterion indicating improvement (decrease) in sched-
ule length for each problem instance when our placement-aware
priority function is used compared to placement-unaware LPF as:

$$100 \times (T_{longest\_path} - T_{heu}) / T_{heu}$$

Figure 8 shows that our placement-aware priority function con-
sistently generates better schedules. Table 2 summarizes the result
for 60 problem instances. Each entry in the table represents data
from a set of instances. As an example, the entry corresponding to
the row labelled v60 and column labelled "Avg gain (16,20)" is
6.86%. This implies that for a set of problem instances where the
graph size is approximately 60 nodes and the resource constraint
was set at 16 and 20 columns, the average improvement in sched-
ule length generated by our heuristic over LPF was 6.86%.

As is clear from Table 2, while a simple longest path heuris-
tic works reasonably well with small graphs and few columns,
our heuristic clearly generates superior (shorter) schedules, both with
increasing graph size and increase in available resources. The key
difference is that LPF also tries to improve schedule length by
Table 3: Schedule length for different HW-SW partitioning of JPEG encoder

</tbody>
</table>

Table 3 presents a summary of schedule length estimates (in ms) generated from various experiments. The first 3 columns A,B,C correspond to experimental data for the given task graph. Column A (16.74ms) represents the first experiment with static HW-SW partitioning (without considering the dynamic nature of HW), B (9.04ms) represents HW-SW partitioning when the HW is partially reconfigurable at run-time, C (9.04ms) corresponds to schedule improvement with optimal prefetch.

We subsequently exposed more parallelism by making multiple copies of tasks like DCT based on our knowledge that data blocks can be independently processed by such tasks. The remaining results in columns D, E, F correspond to experimental data for the finer-grain task graph. Column D (7.21ms) represents the results generated by our heuristic on the finer-grain graph—this is optimal for this representation.

**Heterogenous Architecture**

For the next experiment in Column E (6.82ms) we considered that the resource constraint of 8 columns now included one specialized resource column, i.e., the new resource constraint was a set of 7 CLB columns and 1 resource column. In the schedule generated by our heuristic, some of the tasks are bound to their faster heterogeneous implementations while others are bound to slower homogeneous implementations. This experiment demonstrates the exploration capability of our heuristic in considering multiple task implementations while mapping onto a heterogeneous device with partial dynamic reconfiguration.

While evaluating the schedule length improvement in Column E, a key factor to be noted is our realistic assumption about the reconfiguration overhead for a specialized resource column—on the Virtex-II, a resource column has 64 frames whereas a CLB column has 22 frames leading to a significantly higher reconfiguration overhead for a specialized column. This fact leads to significantly less speedup than would be expected simply from considering execution time difference between homogenous and heterogeneous implementations. Another important observation was that heterogeneity restricts placement significantly and the relative location of the specialized resource column strongly affects the schedule length.

Column F (9.58ms) was our final experiment where we restricted tasks to only their best implementation points. Since the best implementation points are often heterogeneous, the schedule length showed significant degradation because of contention for the dedicated resources.

Overall, our case study confirms the importance of considering physical and architectural (heterogenous) constraints in a HW-SW partitioning algorithm for a partially reconfigurable device.

**Run time of algorithm:** Table 2 also shows the average run-time of our approach (in seconds) for 20–100 tasks given an area-constraint of 20 columns—measurements were done on a 502 Mhz Sparc9 processor (SunOS 5.8). While the run-time of our placement-aware approach grows with increase in area-constraint, we believe that the data, corresponding to our largest experiments, is a fair representation of the expected run-time in reasonable scenarios.

**7. CONCLUSION**

In this paper, we first demonstrated with an exact approach that ignoring linear task placement constraints imposed by a reconfigurable architecture with partial dynamic reconfiguration can result in optimal, but physically unrealizable schedules. We next proposed a placement-aware HW-SW partitioning heuristic that simultaneously partitions, schedules and does linear placement of tasks on such devices. Our approach considers the key issues of configuration prefetch, the bottleneck of a single reconfiguration controller. We conducted a wide range of experiments to validate the quality of solutions generated by our placement-aware heuristic. Placement and consideration of multiple implementations in partitioning make it easy to extend our approach to heterogenous FPGAs. We demonstrate with a case study the exploratory capabilities provided by our approach. Finally, the run-time of our approach is reasonable: task graphs with hundreds of nodes are processed (partitioned, scheduled, placed) in a couple of minutes.

Our approach has powerful capabilities, but there is scope for improvement in our current implementation in both solution quality and in the theoretic algorithmic complexity by investigating sophisticated placement techniques and data structures. Also, our heuristic currently is focused on homogenous implementations—more investigations are required into issues leading to high-quality solutions in heterogeneous scenarios.
