ABSTRACT

As FPGA densities increase, partitioning-based FPGA placement approaches are becoming increasingly important as they can be used to provide high-quality and computationally scalable placement solutions. However, modern FPGA architectures incorporate heterogeneous resources, which place additional requirements on the partitioning algorithms because they now need to not only minimize the cut and balance the partitions, but also they must ensure that none of the resources in each partition is oversubscribed. In this paper, we present a number of multilevel multi-resource hypergraph partitioning algorithms that are guaranteed to produce solutions that balance the utilization of the different resources across the partitions. We evaluate our algorithms on twelve industrial benchmarks ranging in size from 5,236 to 140,118 vertices and show that they achieve minimal degradation in the min-cut while balancing the various resources. Comparing the quality of the solution produced by some of our algorithms against that produced by hMETiS, we show that our algorithms are capable of balancing the different resources while incurring only a 3.3%–5.7% higher cut.

1. INTRODUCTION

In recent years, due to the development of high-quality multilevel hypergraph partitioning algorithms [9, 1], partitioning-based placement has emerged as a promising approach for placing large designs on ASICs. These methods have been shown to be computationally scalable, capable of leading to high-quality solutions, and scale to very large designs [14, 3]. Moreover, as FPGA densities increase, the characteristics of this placement methodology are becoming increasingly important for placing large designs on FPGAs, as well [13].

However, unlike ASIC placement where modules in general can be placed anywhere, and as such, the only constraint that they impose on the partitioning algorithm is that of balancing the area of the cells assigned to different partitions, modern FPGA architectures incorporate heterogeneous resources (*e.g.*, CLBs, Multipliers, RAM blocks, IP Cores [16], *etc*) that can only be placed at specific locations. This places additional constraints on the types of partitionings that need to be computed, as the partitioning algorithm must now ensure that the resources used in each partition can be accommodated by the resources provided at the different regions of the FPGA. For example, a partitioning solution that places most of the FFs on one side of the bisection and most of the RAM blocks on the other side of the bisection, even if it is balanced in terms of the total number of cells on either side of the cut, is not very useful for FPGA placement as it may over-subscribe these two resource types.

As a result, existing partitioning algorithms [9, 1, 4, 15, 5] can not be used to develop partitioning-based placement methods for FPGAs with heterogeneous resources, as they can lead to partitionings that have highly unbalanced resource requirements. To illustrate this, we used a multilevel hypergraph partitioning algorithm (hMETiS [10]) to bisect twelve different circuits synthesized for the Xilinx Vertex II architecture, which contain cells that map to different resources. Various statistics measuring the balance of the different resource types are shown in Table 1. These results show that even though the bisection, in terms of the number of cells assigned to each partition, achieves a balance of 49%-51%, in general, individual resources are considerably more unbalanced.

A previous work [12] attempted to solve partitioning of heterogeneous resources in an FM based framework. However this approach requires network flow computations to calculate/update gain values of FM, limiting the applicability to very small partitioning instances.

In this paper, we present a new class of *multi-resource hypergraph bisectioning algorithms* that are capable of producing a partitioning solution that simultaneously balances the different resources assigned to each one of the partitions and can be used to implement partitioning-based placement methodologies for emerging FPGA architectures. Specifically, we present five different multi-resource partitioning algorithms that are based on the multilevel hypergraph partitioning paradigm. Three of these algorithms solve the problem by balancing the different resources at the same time that they compute the bisection, while the other two are used to post-process a high-quality but potentially unbalanced solution to enforce the

Table 1: The distribution of unbalance factors of different types of cells, for 49%-51% bisection. For the partition to be feasible, unbalance factor of each cell-type must be below 2.0. The column "min ub" shows the minimum unbalance factor, "max ub" shows the maximum unbalance factor, "avg ub" shows average unbalance factor, and "# viol" shows the number of cell-types exceeding the unbalance factor of 2.0.

multiple balancing constraints. We experimentally evaluated the performance of these algorithms on twelve different industrial circuits containing up to 140,118 cells. Our results show that each one of these algorithms is capable of producing solutions that satisfy the multiple balancing constraints and achieve different time-quality trade-offs. Moreover, comparing the quality of the solution produced by some of our algorithms against that produced by hMETIS, we show that our algorithms are capable of balancing the different resources while incurring only a 3.3%–5.7% higher cut.

The rest of the paper is organized as follows. Section 2 defines various concepts and terms that are used in the paper and present a brief overview of the multilevel partitioning paradigm. Section 3 provides a formal definition of the multi-resource partitioning problem. Section 4 describes the various multi-resource partitioning algorithms that we developed. Section 5 presents a comprehensive experimental evaluation of these algorithms. Finally, Section 6 provides some concluding remarks.

2. NOTATION AND BACKGROUND

A *hypergraph* $G = (V, E)$ is a set of vertices V and a set of hyperedges E. Each hyperedge is a subset of the set of vertices V. The *size* of a hyperedge is the cardinality of this subset. A vertex v is said to be *incident* on a hyperedge e, if $v \in e$. Each vertex v and hyperedge e has a weight associated with them and they are denoted by $w(v)$ and $w(e)$, respectively. A circuit/netlist consisting of a set of cells and a set of nets can be directly represented via a hypergraph, whose vertices corresponds to the cells and whose hyperedges corresponds to the nets. Due to this one-to-one correspondence between hypergraphs and netlists we will use the terms vertices/cells and hyperedges/nets interchangeably throughout this paper.

A bisection of V is denoted by a vector P such that $P[i]$ indicates the partition number that vertex i belongs to. The *cut* of the bisection is equal to the sum of the weight of the hyperedges that connect vertices belonging to different partitions. We say that a bisection P of V *satisfies* a *single balancing constraint* specified by $[l, u]$, where $l < u$, iff $l \leq \sum_{v \in V_i} w(v) \leq u$, for each partition V_i. A bisection that satisfies the constraint is called *feasible*, otherwise it is *infeasible*. Given these definitions, the hypergraph bisection problem is formally defined as follows: *Given a hypergraph $G(= V, E)$ and a balancing constraint $[l, u]$, find a feasible bisection P of G that minimizes the cut*. Since there is only a single balancing requirement, this formulation is usually referred to as the single-constraint bisectioning problem [6].

3. PROBLEM DEFINITION

Historically, FPGA devices contained resources of single type (*e.g.*, CLBs) that were uniformly distributed throughout the chip. However, taking advantage of ever-increasing silicon densities, modern FPGA devices are fabricated with multiple types of resources, which allow them to efficiently implement complex and high performance designs. One such example is the recently introduced Virtex II architecture from Xilinx that contains specialized resources such as multiplier and RAM blocks interspersed among CLBs. Similar heterogeneity can be seen in devices such as Altera's Excalibur and Stratix. As a result, design flows created for such modern FPGAs try to proactively make use of these specialized resources in order to obtain better performance and versatility.

For partitioning driven placement to succeed in utilizing these different resource types, the partitioning algorithms need to take them into account and balance each type of cells across the cut lines.

Motivated by this observation we focus on multi-resource aware partitioning, which can be formally defined as follows. Consider an FPGA architecture with m distinct resource types and let $t_1, t_2, \ldots, t_m$ denote the types of cells that need to be matched to the resources labelled as $r_1, r_2, \ldots, r_m$ respectively. Let ${cl_{t_i}}^j$ denote the minimum number of cells of type t_i allowed in partition j, and ${cu_{t_i}}^j$ be the maximum number of cells of type t_i allowed in partition j. Then the multi-resource bisection P of G seeks to minimize the cut subject to:

$$ {cl_{t_i}}^j \leq \sum_{\forall v \in V : P[v]=j \ \ and \ \ t(v)=t_i} 1 \leq {cu_{t_i}}^j, \qquad (1) $$

for $j = 1, 2$, $i = 1, 2, \ldots, m$, and $t(v)$ is the type of cell v. The partitioning that satisfies Equation 1 is referred to as feasible (or *legal*) bisection. Note that this is a general definition of the multi-resource bisection and only the upper bound is usually needed in most cases. Furthermore, when the number of cells of a certain type are small and an odd number, it is sometimes impossible to satisfy the balance constraint. In such cases the balance constraint needs to be relaxed. For example, if there are only 3 cells of a certain type present, then the balance constraint of 49% - 51% is impossible to satisfy, and needs to be relaxed to 33% - 67% for this type of cells, to accommodate them.

4. MULTI-RESOURCE PARTITIONING ALGORITHMS FOR FPGAS

To solve the multi-resource bisectioning problem we developed two classes of multi-resource partitioning algorithms. The first class, computes the overall solution by constructing a bisection that simultaneously balances the multiple resources, whereas the second class, achieves the desired balance by modifying a bisection that was initially obtained using a traditional single-constraint bisectioning algorithm. We will refer to the first class as the *native multi-resource partitioning* algorithms and to the second class as the *multi-resource enforcement* algorithms. The details of the various algorithms in each of these classes are provided in the rest of this section.

4.1 Native Multi-Resource Partitioning Algorithms

We developed three different algorithms, called *multi-phase*, *multi-constraint*, and *multi-phase–multi-constraint* that are capable of di-

rectly computing a partitioning that balances the different resources. These algorithms were motivated by recently developed graph partitioning algorithms for partitioning finite element meshes arising in multi-phase and multi-physics scientific numerical simulations [11, 2]. Specifically, our *multi-phase* algorithm is based on the graph partitioning algorithm proposed in [2], our multi-constraint algorithm is based on the graph-partitioning algorithm proposed in [11], whereas the *multi-phase–multi-constraint* algorithm combines elements from both of these approaches. Details on these algorithms are provided in the remainder of this section.

4.1.1 Multi-Phase Bisection (MP)

The underlying logic behind this algorithm is quite simple. This algorithm uses regular single-constraint partitioning algorithm to partition each type of cells, one type at a time. It also uses the partition information of the already bisected types to influence the bisection process of subsequent types.

In the first step of the algorithm, a series of hypergraphs are constructed denoted by $H_1, H_2, \ldots, H_m$. H_1 contains only the cells of type t_1, H_2 contains only the cells of type t_1 and t_2, H_3 contains only the cells of type t_1, t_2, and t_3, and so on. The hyperedges for these sub-hypergraphs are reconstructed based on the hyperedge information of the original hypergraph. The weights of the reconstructed nets are adjusted to reflect the reduced number of cells that are incident on these nets. Specifically, the weight for reconstructed net e', $w(e')$ is calculated as $w(e) * (|e'|/|e|)$. Also, the reconstructed nets with the cardinality of one are ignored.

In the second step, each of these sub-hypergraphs is bisected one after the other, while using the information from previously bisected hypergraphs to influence the current bisection process. Initially, the bisection P_1 of H_1 is obtained by hMETIS using the balance constraint $[cl_{t_1}, cu_{t_1}]$. Then, based on P_1, the cells of type t_1 in H_2 are fixed into their respective partitions and their weights set to zero. For computational efficiency, the fixed cells are collapsed into two fixed dummy cells dv_1 and dv_2 with zero area, for their respective partitions numbered as 1 and 2. After this, hMETIS is used to obtain partition P_2 of hypergraph H_2 with the balance constraint $[cl_{t_2}, cu_{t_2}]$. The bisection P_2 is legal as the cells of type t_1 obey the bound specified by $[cl_{t_1}, cu_{t_1}]$ (fixed cells), and cells of type t_2 obey the bound specified by $[cl_{t_2}, cu_{t_2}]$ (enforced by the partitioner). To obtain the partition P_3 of hypergraph H_3, we fix the cells of type t_1 and t_2 into their respective partitions and collapse them to create two fixed dummy cells (dv_1, dv_2) of zero area and then use hMETIS with the balance constraint of $[cl_{t_3}, cu_{t_3}]$. By a similar argument, P_3 can be shown to be legal. This process is repeated until P_m of H_m (original hypergraph) is obtained. P_m satisfies the balance constraints for each type of cells individually and hence it is a legal solution.

Since it is easier to influence the bisection of a smaller number of cells from the partition information of a larger number of cells, we re-order the types in decreasing size. That is, t_1 corresponds to the cell type that contains the largest number of cells, t_2 corresponds to the second largest, and so on.

4.1.2 Multi-Constraint Bisection (MC)

The multi-resource partitioning problem can be naturally solved using the multi-constraint partitioning problem initially developed in the context of graphs. Specifically, using the general framework introduced in [11], we extend the hypergraph model so that each vertex v has a weight vector $\boldsymbol{w}(v)$ of size m associated with it. The ith component of this vector $w_i(v)$ corresponds to the weight associated with the ith constraint. This model assumes, without loss of generality, that the weight vectors of the vertices satisfy the property that $\sum_{\forall v \in V} w_i(v) = 1.0$ for $i = 1, 2, \ldots, m$. Using a framework analogous to that used for single-constraint problems, we allow for m lower- and upper-bound constraints on the size of each partition (l_i, u_i) for $i = 1, 2, \ldots, m$, such that $0 < l_i < u_i$ and $l_i + u_i = 1$. Given these definitions, the multi-constraint hypergraph bisection problem is formally defined as follows:

Compute a bisection P of V that minimizes the sum of the weight of the hyperedges that span multiple partitions subject to the constraint that

$$l_i \leq \sum_{\forall v \in V : P[v]=j} w_i(v) \leq u_i,$$

where $j = 1, 2$ and $i = 1, 2, \ldots, m$ represent the different vertex weights. This multi-constraint partitioning problem tries to find a bisection such that each weight is individually balanced within the specified lower- and upper-bound tolerances. For example, multi-constraint partitioning can be used to bisect a netlist such that both partitions are balanced in terms of area and power consumption.

Using the multi-constraint partitioning problem formulation the multi-resource partitioning problem can be formulated as follows. Given a multi-resource hypergraph $G = (V, E)$ with m different vertex types, then each vertex $v \in V$ is assigned a vector of m vertex weights $\boldsymbol{w}(v)$, such that $w_{t(v)}[v] = 1$ and $\forall i \neq t(v), w_i(v) = 0$. It is easy to see that a feasible multi-constraint solution of this hypergraph will correspond to a feasible solution for the multi-resource partitioning problem, as well.

We have developed a multi-constraint hypergraph partitioning algorithm that follows the traditional structure of the multilevel partitioning paradigm. Specifically, we developed algorithms for the coarsening, initial partitioning, and uncoarsening phases that combine elements of the single-constraint hypergraph partitioning algorithms in hMETIS with the multi-constraint extensions, initially introduced for graph partitioning [11]. Due to space constraints, in this paper we will only describe the multi-constraint partitioning refinement algorithm used during the uncoarsening phase as it is an integral part in many of the approaches presented in this paper. The interested readers should refer to [11, 8, 6] for further details.

Multi-constraint Refinement (MC-FM). We developed a multi-constraint bisection refinement algorithm, called MC-FM, which is based on the widely used single-constraint FM algorithm [7] and operates as follows. For each one of the two partitions, it maintains m priority queues, where m is the number of weights. A vertex belongs to only a single priority queue depending on the relative order of the weights in its weight vector. In particular, a vertex v with weight vector $(w_1(v), w_2(v), \ldots, w_m(v))$, belongs to the jth queue if $w_j(v) = \max_i(w_i(v))$. Given these $2m$ queues, the algorithm starts by initially inserting all the vertices to the appropriate queues according to their gains. Then, it proceeds by selecting one of these $2m$ queues, picking the highest gain vertex from this queue, and moving it to the other partition. The queue is selected as follows. If the current bisection represents a feasible solution, then the queue that contains the highest gain vertex among the $2m$ vertices at the top of the priority queues is selected. On the other hand, if the current bisection is infeasible, then the queue is selected depending on the relative weights of the two partitions. Specifically, if A and B are the two partitions, then the algorithm selects the queue corresponding to the largest $w_i(x)$ with $x \in \{A, B\}$ and $i = 1, 2, \ldots, m$. If it happens that the selected queue is empty, then the algorithm selects a vertex from the non-empty queue corresponding to the next heaviest weight *of the same partition*. For example, if $m = 3$, $(w_1(A), w_2(A), w_3(A)) = (.43, .60, .52)$, and $(w_1(B), w_2(B), w_3(B)) = (.57, .4, .48)$, the algorithm will select the second queue of partition A. If this queue is empty, it will then try the third queue of A, followed by the first queue of A. Note

that we give preference to the third queue of A as opposed to the first queue of B, even though B has more of the first weight than A does of the third. This is because our goal is to reduce the second weight of A. If the second queue of A is non-empty, we will select the highest gain vertex from that queue and move it to B. However, if this queue is empty, we still will like to decrease the second weight of A, and the only way to do that is to move a node from A to B. This is why when our first-choice queue is empty, we then select the most promising node from the same partition that this first-queue belongs to.

4.1.3 Multi-Phase Multi-Constraint (MPMC)

This algorithm improves upon MP (Section 4.1.1), by incorporating two additional heuristics. First is the introduction of pseudo hyperedges into the sub hypergraphs ($H_1, H_2, \ldots, H_m$) to retain the overall structure of the original hypergraph, and the second heuristic is the application of MC-FM based refinement for partitions P_i, for $i = 2, 3, \ldots, m$.

During the generation of sub hypergraphs $H_{m-1}, \ldots, H_2, H_1$, cells and hyperedges are progressively removed starting from original hypergraph (H_m). This damages the information on the overall structure of H_m progressively. If the structure of H_1 is largely similar to the overall structure of H_m, then intuitively the bisection P_1 will correspond to a better bisection of H_m. One way to retain the overall structure of H_m, is by introducing pseudo hyperedges that maintain the relative connectivity between the sections of the hypergraph. We add the hyperedges in the following way. When a vertex is removed, its neighbors are analyzed to determine how closely each neighbor is connected to the removed vertex. If the connectivity is larger than 10% of average hyperedge weight, then these neighbors are considered to be connected to the removed vertex and are connected by a light weight (typically 10% of average hyperedge weight) pseudo hyperedge. The connectivity to neighbors is estimated by representing each hyperedge by a clique of edges each with the weight of $w(e)/(|e|-1)$ and by summing the weights of edges common to each neighbor and the removed vertex. When determining the connectivity, previously added pseudo hyperedges are *not* taken into consideration. These settings work very well for our purpose as evident in Section 5 but may require fine tuning depending on the application.

The other enhancement of MP stems from the observation that the cells of already bisected types remain fixed throughout the flow, but can potentially be moved to further improve the cut. In order to achieve that we apply a few iterations of MC-FM to bisections P_i, for $i = 2, 3, \ldots, m$.

4.2 Multi-Resource Enforcement Algorithms

In analyzing the characteristics of the various multi-resource circuits we discovered that the different types of vertices are reasonably well-distributed throughout the underlying hypergraph. This suggests that the bisections produced by single-constraint partitioning algorithms, even though they will not be perfectly balanced, they will not be arbitrarily unbalanced either. Moreover, since these partitionings can be computed using state-of-the-art multilevel schemes, they will have small cuts. Motivated by this observation, we developed two schemes that take as input a min-cut single constraint partitioning and try to enforce the various multi-resource balanced constraints.

4.2.1 Single-Constraint Direct-Balancing (SCDB)

In this method, we use the multilevel single-constraint partitioner hMeTiS to seed the initial bisection. Then we use an explicit balancing algorithm to balance the multiple resources in a single step. This multi-constraint balancing algorithm operates very similar to MC-FM (described in Section 4.1.2), except that it gives priority to finding a balanced bisection rather than minimizing cut. This balancing step tends to increase the cut, especially when the number of constraints is large. Hence, in order to achieve a high-quality partitioning, it is important to further refine this feasible solution. For this reason, our algorithm performs a single iteration of the MC-FM multi-constraint refinement algorithm in an effort to improve the cut quality after obtaining a feasible bisection.

4.2.2 Single-Constraint Multi-Phase Balancing (SCMB)

As in the previous algorithm (SCDB), we use hMeTiS to obtain an initial partition. From this initial partition, we construct a series of sub hypergraphs $H_x, H_{x+1}, \ldots, H_m$, such that the hypergraph H_x contains all the cells belonging to the types that are already balanced in this initial bisection. The sub hypergraphs $H_{x+1}, H_{x+2}, \ldots, H_m$, progressively contain additional types of cells, whose types are re-ordered in increasing unbalanced order. For example, the unbalanced type present in H_{x+1} is less unbalanced than the additional type present in H_{x+2}. Each of these hypergraphs are then bisected to obtain P_i (for $i = x+1, \ldots, m$) in the way described in Section 4.1.1. After each unbalanced type is balanced we also apply an iteration of MC-FM to each P_i, in order to capitalize on the perturbation caused during balancing as well as to allow previously fixed cells the ability to move.

4.3 Additional Improvements

After the bisection of the original hypergraph has been computed, it is possible to further improve the cut by applying a multi-constraint V-cycle. Multi-Constraint V-cycle consists of two components, *restricted multi-constraint coarsening* and multi-constraint refinement. The restricted multi-constraint coarsening step differs from regular multi-constraint coarsening by the presence of an additional requirement that any two vertices that are collapsed together belong to the same partition. The information regarding the partitioning is thus preserved during the creation of successive approximate hypergraphs. This coarsening scheme is a multi-constraint version of restricted coarsening presented in [9]. The second component of the V-cycle is same as the multi-constraint refinement presented in Section 4.1.2.

5. EXPERIMENTS

We experimentally evaluated our multi-resource aware partitioning algorithms on an industrial benchmark suite consisting of twelve large designs synthesized for Xilinx Virtex II architecture. The types of cells consist of sub CLB elements such as LUTs, FFs, MUXes, control gates and non CLB elements such as RAM Blocks, DCMs, IOBs, Multipliers etc. The details of these benchmarks are listed in Table 2. The column labeled as "# types" shows the number of distinct types of cells available on that particular benchmark. The columns labeled as "min" shows minimum number of cells of any type for that benchmark, and similarly the "max" and "avg" columns provide the details of distribution of number of cells in each hypergraph.

To evaluate the quality of the solutions obtained by the various multi-resource partitioning algorithms, we used hMeTiS (version 1.5.3 [10]) to obtain single-constraint bisections of the different hypergraphs. These solutions were obtained using hMeTiS's default parameters (including V-cycle at the end). Furthermore, to make such quality comparisons easier, we computed the Average Ratio of Quality (ARQ) of each algorithm against that obtained by hMeTiS. To ensure the meaningful averaging of these ratios, we first took the $\log_2$-values of these ratios, then calculated their mean μ, and then used 2^{μ} as their average. This method ensures that ratios corresponding to comparable degradations or improvements (*i.e.*,

ratios that are less than or greater than one) are given equal importance. The ARQ number larger than 1.0 indicates degradation in quality.

To ensure the statistical significance of our experimental results, for both hMETiS and each one of the five multi-resource partitioning algorithms we report average min-cut of ten runs.

5.1 Comparison of Native Algorithms

Tables 3 and 4 show the results obtained by the various native multi-resource partitioning algorithms (described in Section 4.1) for 49%–51% and 45%–55% balance, respectively. Each of these tables shows the average minimum cuts obtained by the MP, MC, and MPMC multi-resource partitioning algorithms under two different scenarios. In the first scenario, the solution obtained by these algorithms was kept as it was, whereas in the second scenario, the solution was further refined by performing a V-cycle refinement step (as discussed in Section 4.3).

The columns labeled "hMETiS" show the average min-cut obtained by hMETiS for either 49%–51% or 45%–55% balance. Note that hMETiS's bisections will not necessarily solve the multi-resource problem, as they do not account for the different vertex types.

Finally, the rows labeled "ARQ" provides the average ratio of quality of each algorithm to hMETiS's results (computed using the scheme described in the previous section), and the rows labeled "Time" shows the amount of time required by the multi-resource partitioning algorithms relative to that required by hMETiS. Numbers less than one represent run-times that are smaller than that of hMETiS, whereas numbers greater than one represent higher run-times.

Comparing the results in these tables we can see that all schemes produce solutions whose cuts are worse than those produced by

Table 4: Performance of algorithms as an average of 10 runs for 45%-55% balance constraint.

hMETiS. This should not be surprising, as hMETiS solves the single-constraint bisectioning problem which, in general, does not solve the multi-resource partitioning problem.

Comparing the solutions produced by the various multi-resource partitioning algorithms we can see that there is a considerable amount of variability on the quality of the final solutions. In particular, in the absence of V-cycle refinement, the quality of the solutions produced by MP are significantly worse than those produced by either MC or MPMC. On the average, the 49%–51% cuts produced by MP are 4.4 times worse than those produced by the single-constraint hMETiS, whereas the cuts produced by MC and MPMC are only 55.4% and 50% worse than hMETiS's cuts, respectively. Similar trends can be also observed for the 45%–55% cuts, as well. These results illustrate that the multi-constraint algorithm (MC) and the modifications to the multi-phase partitioning algorithm implemented in the MPMC algorithm, lead to superior solutions.

Comparing the results without and with V-cycle refinement we see that the overall quality of all three algorithms improves by using V-cycle refinement. However, the overall rate of improvement is different for different schemes. The MP algorithm gains the most, whereas the MPMC algorithm gains the least. We believe that the reason for that is the fact that the solutions of MC and MPMC are already of reasonable high quality, and thus, there is relatively little room for improvement. However, because MP's initial solution is considerably worse, by applying a V-cycle refinement, we can achieve dramatic quality improvements. As a result, the 49%–51% solution for MP now becomes only 88.2% worse than that of hMETiS.

Finally, comparing MC with MPMC we can see that the latter leads to consistently better solutions, which are on the average 5%–10% better than those obtained by MC. However, this quality advantage comes at the expense of higher computational requirements. In general, MPMC requires 2.5 to 5.0 times more time than that required by MC. Note that the reason that the run-times of MP and MC without V-cycle are in general smaller than that of hMETiS is because hMETiS does perform a V-cycle refinement at the end.

5.2 Comparison of Enforcement Algorithms

Tables 5 and 6 show the results obtained by the various enforcement-based multi-resource partitioning algorithms (described in Section 4.2) for 49%–51% and 45%–55% balance, respectively. Each of these tables shows the average minimum cuts obtained by the SCDB and SCMB partitioning algorithms without and with V-cycle refinement. In addition, the columns labeled "hMETiS" show the results obtained by hMETiS (which are identical to those shown in Tables 3 and 4), the rows labeled "ARQ" provide the average ratio of

Table 6: Performance of algorithms combined with multi-constraint V-cycle as an average 10 runs for 45%-55% balance factor.

quality of each algorithm to hMETIS's results, and the rows labeled "Time" show the amount of time required by the multi-resource partitioning algorithms relative to that required by hMETIS.

Comparing the solutions produced by the two sets of enforcement-based multi-resource partitioning algorithms we can see that, unlike the native algorithms, there is relatively little variation between the performance achieved by them. Specifically, the performance difference between the two schemes is less than 7%, on the average. However, the SCMB algorithm is consistently better than SCDB, leading to better solutions in 31 out of the 48 different experimental data-points. Comparing the results without and with V-cycle refinement we see that as it was the case with the native algorithms, the overall quality of the two algorithms improves, as well. However, those improvements are relatively small, ranging on the average between 2% and 5%. Finally, comparing the amount of time required by these algorithms we can see that SCMB is slower than SCDB, but in most cases the difference is small.

5.3 Overall Comparisons

Comparing the performance achieved by the various multi-resource partitioning algorithms we can see that in almost all the cases, the enforcement-based algorithms lead to solutions that have lower cut than those obtained by the native multi-resource partitioning algorithms. For example, the best-performing enforcement-based scheme SCMB outperforms the best-performing native scheme in 41 out 48 data-points. Moreover, the cut differences are considerable, and on the average SCMB leads to cuts that are 13%–32% better than that of MPMC. However, this performance advantage is also data-set dependent, and the relative performance of the various schemes can change for different benchmarks.

Finally, comparing the performance achieved by SCMB against that achieved by the single-constraint hMETIS, we can see that the overall increase in the cut resulting by solving the multi-resource partitioning problem, is quite small. For example, if we consider SCMB's results with V-cycle refinement we can see that on the average the cut increases by only 5.7% and 3.3% for the 49%–51% and 45%–55% balance constraints, respectively.

6. CONCLUSION

In this paper we presented two classes of multi-resource aware partitioning algorithms for enabling partitioning-based placement methods for FPGA architectures with heterogeneous devices. These algorithms are very effective in minimizing the cut while satisfying multiple balancing requirements with acceptable computational effort. The average cut of the most effective algorithm is only 5.7% and 3.3% worse than that of the state-of-the-art partitioning tool hMETIS [10] for 49%–51% and 45%–55% balance constraints, respectively. Moreover, their additional computational requirements are small, requiring only two to three times more time than hMETIS.

These results indicate that high-quality partitionings are feasible for designs with multiple resource requirements, suggesting that partitioning-based placement methods can be used for placing such designs on modern FPGA architectures.
